MODULE 7: PEDIATRIC URINARY TRACT INFECTIONS

KEY WORDS: Cystitis, renal abscess, dysuria, hematuria, pyelonephritis, hydronephrosis, UTI

LEARNING OBJECTIVES

At the end of this clerkship, the medical student will be able to:

1. Outline the socioeconomic impact and epidemiologic characteristics of pediatric UTIs
2. Describe the differences in clinical presentation between lower and upper UTI’s
3. Outline the risk factors associated with viral and fungal pediatric UTI’s
4. Delineate 5 congenital/anatomical causes and 3 acquired causes of pediatric UTIs
5. List 3 possible causative organisms in non-bacterial, pediatric UTIs
6. Summarize the diagnostic evaluation of pediatric UTIs
7. Summarize the management approaches for congenital/anatomic and acquired causes of pediatric UTIs
8. Outline the treatment goals and complications associated with antibiotic prophylaxis for pediatric UTIs
9. Describe the anatomic and functional sequelae of untreated pediatric UTIs

EPIDEMIOLOGY

Pediatric UTI’s are a major health care issue. Urinary tract infections (UTIs) affect 3% of children every year. Annually, pediatric UTI’s account for over 1 million office visits in the U.S. (0.7% of all physician visits by children). These children are usually first seen by their primary care physicians, their pediatricians, or their family practitioner. Each year there are approximately 13,000 pediatric admissions for pyelonephritis, with inpatient costs exceeding $180 million. Throughout childhood, the risk of UTI is 8% for girls and 2% for boys. During the first year of life, more boys than girls get UTI’s, with a tenfold increased risk for uncircumcised compared to circumcised boys.

CLINICAL PRESENTATION

Most urinary tract infections are due to dysfunctional voiding leading to a moist and irritated perineal area and bacteria subsequently entering the urethra.
The anatomic location of the UTI is germane to etiology and clinical presentation. Regardless of UTI location, infants and many young children cannot describe their symptoms; hence it is critical to understand the observable signs and symptoms of infection to make the diagnosis. Lower UTI’s include bladder infections (cystitis), whereas upper UTI’s include pyelonephritis and perinephric and renal abscess. Cystitis is second in frequency only to respiratory infection as a reason for pediatric medical visits. Classic symptoms of cystitis include urinary frequency, urgency, dysuria, hematuria, suprapubic pain, sensation of incomplete emptying, and even incontinence. Non-specific symptoms can include poor feeding, irritability, lethargy, vomiting, diarrhea, ill appearance, and abdominal distension (Table 1). Fever and flank pain are unusual symptoms for lower UTI.

Pyelonephritis, and to a lesser degree renal abscesses, typically begin as a lower UTI that proceeds to an upper UTI as the infections ascend. However, pyelonephritis and renal abscesses can also result from the rare hematogenous spread of infection (e.g., bacteremia). Symptoms that occur with upper UTI’s overlap those for cystitis, in part because cystitis is common in both. In upper UTI’s, flank pain and fevers (classically intermittent and >39°) are more pronounced and important (Table 1).

It is important to remember that the vast majority of UTI’s are caused by perineal bacteria ascending from the urethra, into the bladder, and then up the ureters to the kidney.
Figure 1: Algorithm for management of pediatric UTI (From: Marotte, Lee, Shortliffe, AUA Update Series vol 24; Lesson 19, 2005).
A thorough history from parents, and the child if possible, and a physical examination are essential in the evaluation of pediatric UTI. Dipstick urinalysis is the most common initial laboratory testing, and may be the most cost-effective screen for infant UTI. Urine cultures and blood cultures (if sepsis is suspected) are the mainstays of diagnosis. Urine from bagged and voided specimens are easier for the child, but have significant false positive rates because of contamination with skin flora (up to 63% for the bag method).

Urethral catheterization and suprapubic aspiration provide the best urine specimens for the diagnosis. The standard definition for bacterial UTI from a voided urine culture is 10^5 colony forming units/mL.

The likelihood of UTI can also be estimated based on urine bacterial counts and collection method. The presence or absence of pyuria on urinalysis, along with a urine culture, help make the diagnosis of pediatric UTI (Figure 1). Pyuria with a negative urine culture suggests viral infection, infection with fastidious organisms such as mycobacterium or haemophilus, or noninfectious cystitis. The lack of pyuria and a negative urine culture suggests a non-infectious etiology for cystitis. A positive urine culture along with pyuria likely represents bacterial or fungal infection. A positive urine culture without pyuria may indicate contamination or an immunosuppressed host.

Treatment of the UTI should include at least a 7 to 10 day course of culture appropriate antibiotic based on culture proven sensitivity. It is important to make sure the child remains well hydrated. Vomiting and an inability to tolerate fluids or oral medications as well as uncontrollable fever are indications for admission to the hospital for IV fluids and IV antibiotics. When a child does not appear to improve after 2 to 4 days of the appropriate antimicrobial therapy with their first UTI, you should perform a renal & bladder ultrasonography to insure there is no renal or ureteral obstruction.

After establishing the diagnosis of UTI, children require additional testing to determine if there are congenital abnormalities contributing to their infection. This is important as eradication of UTI with antibiotics may not be possible without correction of underlying structural abnormalities. In addition, the early diagnosis of anatomically based UTI’s can prevent or ameliorate long-term sequelae of persistent or recurrent infections.

The American Urologic Association has suggested guidelines for radiologic imaging of children with UTI’s. Urinary tract imaging is recommended in a febrile infant or young child between the ages of 2 months and 2 years with a first documented UTI. Typically this involves a renal and bladder ultrasound and a voiding cystourethrogram (VCUG) (Figure 2)
The evidence supporting the use of VCUG for older children is less compelling. Imaging is indicated if patients have known anatomic structural abnormalities, unusual uropathogens such as *Proteus* or tuberculosis, fail to improve with appropriate antimicrobial therapy, or have an unclear source of infection. VCUG should be performed as soon as a child is infection-free and bladder irritability has passed, since delaying the VCUG is associated with losing patients to follow-up. Other radiologic studies, including computerized tomography (CT), magnetic resonance imaging (MRI), intravenous urography (IVU), and Dimercaptosuccinic acid (DMSA) and Technetium (Tc)-99 m mercaptoacetyl triglyceride (MAG-3) scans have specific indications that will be discussed further.

**Fungal and Viral UTI**

Fungi and viruses can also cause cystitis in certain settings and with associated risk factors. Fungi, such as *Candida*, are the second most common cause of nosocomial UTI in children, and can spread systemically and can be life-threatening. Risk factors for fungal UTI’s include the use of invasive devices (IV’s, drains, catheters), previous broad-spectrum antibiotic exposure, and systemic immunosuppression. A true candidurial infection can be difficult to diagnose, since it can represent colonization, contamination, or infection, and may or may not have associated symptoms. Suggestive diagnostic criteria include: Lack of pyuria and >10⁴ colony forming units/mL (in neonates) from a urine culture obtained by urethral catheterization. The potential for candiduria to develop into invasive candidiasis in the neonatal intensive care unit (NICU) is significant. Risk factors for this progression include prematurity, congenital urinary tract abnormalities, parenteral nutrition, respiratory intubation, and umbilical artery or intravenous catheterization. Furthermore, the kidney is the most commonly affected organ in candidiasis, with “fungus balls” representing a life-threatening infection. As such, renal and bladder sonography is important in the evaluation of neonates with candiduria.

There is no consensus regarding the treatment of pediatric candiduria. Measures include stopping antibiotics, removing or changing indwelling catheters, and antifungal therapy. Commonly used antifungal agents include oral fluconazole and
parenteral or intravesical amphotericin B. In patients with obstruction or failure to improve with medical management, urgent percutaneous nephrostomy tube placement to drain the kidney may be needed. Additional measures include amphotericin B irrigation of the nephrostomy tube, or even nephrectomy in severe cases.

Viral cystitis represents another form of non-bacterial UTI affecting children. Adenovirus types 11 and 21, influenza A, polyomavirus BK, and herpes simplex viruses can cause irritative voiding symptoms, hemorrhagic cystitis and even vesicoureteral reflux or urinary retention. In non-immunized or immunosuppressed children, herpes zoster cystitis presents similarly. Fortunately, these forms of cystitis are self-limited. Immunosuppressed children undergoing kidney or bone marrow transplantation, or those receiving chemotherapy are especially susceptible to viral cystitis, including those caused by cytomegalovirus and adenoviruses 7, 21, and 35. Antivirals such as ribavirin and vidarabine may be helpful when viral cystitis is diagnosed.

**ANTIBIOTIC TREATMENT AND PROPHYLAXIS**

Antibiotic regimens for children with UTI consist of short treatment courses for acute infections and prophylaxis for chronic conditions. The most common pathogen isolated in children with uncomplicated cystitis is *Enterobacteriaceae*. Accordingly, frequently used antibiotics for prophylaxis and treatment include trimethoprim (with or without sulfonamide) and cephalexin. Although Nitrofurantoin is a good antibiotic choice for uncomplicated UTI’s in children, it is not a good option for treatment of a febrile UTI, as it only achieves therapeutic levels in the urine but not in renal parenchymal tissue. Prolonged antibiotic use can alter gut and periurethral flora, leading to bacterial resistance. As an example, children on antibiotic prophylaxis have a higher incidence of UTI due to *Enterobacter*, *Klebsiella*, and *Proteus*. In addition, widespread use of antibiotics in certain communities has led to increased bacterial resistance to trimethoprim, cephalothin, cephalexin, ampicillin, and amoxicillin. Clearly, antibiotics should be used judiciously to curb increasing bacterial resistance (Table 2).

(From: Marotte, Lee, Shortliffe, AUA Update Series vol 24; Lesson 19, 2005).

Antibiotic prophylaxis is currently controversial for many urologic conditions. Adolescent girls who are sexually active and susceptible to post-coital cystitis are likely better served by taking short courses of antibiotic treatment when symptoms occur and taking brief, post-intercourse prophylaxis rather than using long-term, prophylactic antibiotic therapy.

**SEQUELAE**

Acute sequelae of pediatric bacterial UTI include the spread of infection outside the urinary tract, resulting in epididymitis or orchitis in boys, and sepsis. The most common serious sequelae of pediatric UTI is that due to pyelonephritis. Pyelonephritogenic scarring with renal parenchymal damage occurs more commonly in children than adults. Renal scarring from pyelonephritis appears to be influenced by several factors: age, treatment, host immunity, bacteriuria and vesicoureteral reflux, and urinary tract pressures. Future hypertension occurs in at least 10-20% of children with pyelonephritogenic scarring. Children with recurrent pyelonephritis may also develop progressive renal insufficiency without a UTI symptoms. End-stage renal disease from reflux nephropathy (pyelonephritogenic scarring in the setting of vesicoureteral reflux, discussed below) accounts for 7-17% of end-stage renal disease worldwide, and 2% of cases in the U.S.

Chronic pyelonephritis results from persistent infection after acute pyelonephritis and can result in pyonephrosis, xanthogranulomatous pyelonephritis (XGP), and renal parenchymal scarring with hypertension and renal insufficiency. The accumulation of purulent debris in the renal pelvis and urinary collecting system, known as pyonephrosis, occurs when pyelonephritis is accompanied by urinary tract obstruction.
Pyonephrosis requires appropriate antimicrobial therapy and prompt drainage of the urinary tract with percutaneous nephrostomy tube placement or retrograde catheterization.

XGP is a very rare clinical entity in children affecting < 1% of cases with renal inflammation. Like pyonephrosis, it develops in the setting of chronic obstruction and infection. The most common pathogens causing XGP are *Proteus* and *E. coli*. XGP is usually unilateral and may extend diffusely throughout the affected kidney and even into the retroperitoneum and cause fibrosis of the great vessels. Radiographically, it can be mistaken for childhood renal tumors. Histologically, the XGP kidney shows evidence of pyonephrosis and xanthoma cells, which are foamy, lipid-laden macrophages. Treatment often involves nephrectomy, as well as prolonged antibiotics.

**Dysfunctional Voiding Syndrome**

Dysfunctional voiding syndrome refers to poor function of the lower urinary tract in the absence of any apparent organic cause. In broad terms, dysfunctional voiding is lack of coordination between bladder muscle (detrusor) function and external sphincter activity. Two major categories of children with dysfunctional voiding are those with “lazy”, high capacity bladders with little sensation and contractile activity, and those with overactive bladders that lead to frequency and urgency. Dysfunctional voiding in children with overactive bladders is thought to be due to poor cortical control over inhibition of reflex bladder contractions. Certainly, behavior is crucial to the pathophysiology of most types of dysfunctional voiding. Dysfunctional voiding can lead to secondary vesicoureteral reflux VUR, and may be exacerbated by chronic constipation because of alterations in pelvic floor activity caused by impacted stool. These factors are thought to contribute to bacteriuria and UTI. Diagnostic studies that are helpful in children with dysfunctional voiding include renal sonography, which can detect hydronephrosis in severe cases, VCUG, which can reveal VUR, a KUB, which can show impacted stool, and urodynamics. Treatment of dysfunctional voiding consists of behavioral modification (i.e., timed voids), bowel regimens, anticholinergic medications, and occasionally short-term prophylactic antibiotics. Many children that develop UTI’s also have congenital anatomic abnormalities that contribute to them.

**Congenital Causes of UTI**

*Vesicoureteral Reflux*

Vesicoureteral reflux represents an anatomic abnormality that contributes to UTI’s. Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder into the ureter and, often, into the renal collecting system. Approximately 40% of children...
with UTI are subsequently diagnosed with VUR. Primary VUR results from a congenital abnormality of the ureterovesical junction. The ureteral tunnel within the bladder wall should be 5 times as long as it is wide to prevent urine from refluxing. Secondary VUR is caused by high pressure voiding due to neuropathic bladder, posterior urethral valves or dysfunctional elimination syndrome. VUR is also a risk factor for pyelonephritis, with potential for renal injury.

Figure 3: A, A refluxing ureterovesical junction has the same anatomic features as a nonrefluxing orifice, except for inadequate length of the intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. B, Ureterovesical junction in longitudinal section. 1, Photomicrograph; 2, diagrammatic representation. The ureteral muscularis (u) is surrounded by superficial (ss) and deep (ds) periureteral sheaths that extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle (t). The relationship of the superficial sheath to the vesical muscularis (v) is clearly seen. Transverse fascicles in the superior lip of the ureteral orifice belong to the superficial and deep sheaths. No true space separates ureter from bladder. (A, From Glenn J [ed]: Urologic Surgery, 2nd ed. New York, Harper & Row, 1975; B, from Elbadawi A: Anatomy and function of the urethral sheath. J Urol 1972;107:224.)

(FROM: CAMPBELL-WALSH UROLOGY, 9TH EDITION)

The radiographic diagnosis of VUR is primarily made based on upper tract urinary reflux observed on VCUG. Finding hydronephrosis on renal sonography is inconsistent and not diagnostic of VUR. DMSA scans are used to assess renal cortical function and monitor for renal scarring. Children with VUR may be managed either medically or surgically, and controversy exists regarding the optimal treatment. Medical management encompasses daily antibiotic prophylaxis and periodic radiologic reassessment of the urinary tract, since many children spontaneously resolve VUR.
Likelihood of outgrowing VUR

Figure 5 A, Percent chance of persistence of grades I, II, and IV reflux for 1 to 5 years after initial evaluation. B, Percent chance of persistence of grade III reflux by age for 1 to 5 years after initial evaluation. (From American Urological Association: Report on the Management of Vesicoureteral Reflux in Children. Baltimore, American Urological Association, Pediatric Vesicoureteral Reflux Clinical Guidelines Panel, 1997.)

Copyright 2007 by Saunders, an imprint of Elsevier Inc.

Surgical treatment of primary VUR includes open or laparoscopic ureteral reimplantation and subureteric endoscopic injection of various substances, including dextranomer-hyaluronic acid copolymer.
Figure 6 Cohen cross-trigonal technique, unilateral reimplantation. After the ureter is freed (A), a submucosal tunnel is made, with the new mucosal hiatus just above the contralateral ureteral orifice (B). (From Retik AB, Colodny AH, Bauer SB: Pediatric urology. In Paulson DF [ed]: Genitourinary Surgery, vol 2. New York, Churchill Livingstone, 1984, p 764.)

(FROM: CAMPBELL-WALSH UROLOGY, 9TH EDITION)

Figure 7 Cohen cross-trigonal technique, bilateral reimplant. A, The more superior ureter is tunneled transversely, with its new orifice just above the contralateral orifice. B, The other ureter is tunneled inferiorly, with its new orifice located at the inferior-most portion of the contralateral hiatus. (From Retik AB, Colodny AH, Bauer SB: Pediatric urology. In Paulson DF [ed]: Genitourinary Surgery, vol 2. New York, Churchill Livingstone, 1984, p 765.)

(FROM: CAMPBELL-WALSH UROLOGY, 9TH EDITION)
Because secondary VUR has other causes than simple anatomical ones, it is imperative that these causes are ruled out before antireflux surgery is performed.

The NIH is currently performing a prospective randomized, double-blinded, placebo-controlled study randomizing children with reflux to antibiotic prophylaxis or placebo to determine if prophylactic antibiotics reduce the risks of renal scar formations in children with VUR. [http://www.cscd.unc.edu/rivur/]

**Ureteropelvic Junction Obstruction**

Ureteropelvic junction (UPJ) obstruction accounts for 64% of children born with hydronephrosis. UPJ obstructions are most commonly diagnosed during prenatal maternal-fetal ultrasonography. This condition results from poor peristalsis of the UPJ or an anatomic abnormality consisting of either an “intrinsic,” narrow segment with muscular discontinuity, or an “extrinsic” anatomic cause from aberrant vessels or a high insertion of the ureter into the renal pelvis (Figure #). Presenting symptoms include hematuria, UTI, abdominal mass or pain, nausea, or flank pain which worsens with diuresis (also known as Dietl’s crisis). Evaluation of UPJ obstruction includes renal ultrasonography, a VCUG to rule out VUR (33% of cases), and a MAG-3 diuretic renogram to look for delayed drainage on the affected.

Figure 9 Example of ureteropelvic junction obstruction. (From: kidney.niddk.nih.gov)
Management of UPJ obstruction is dictated by age at diagnosis, symmetry of renal function, severity and stability of hydronephrosis, severity of delayed drainage, and degree of associated symptoms. In some asymptomatic children, UPJ obstruction will resolve spontaneously with expectant management. For many children, however, surgical repair is needed through either open surgical pyeloplasty, the traditional approach, or newer techniques such as laparoscopic pyeloplasty, robot-assisted laparoscopic pyeloplasty, and percutaneous and retrograde endopyelotomy.

**Ureteroceles**

A ureterocele is a cystic dilatation of the terminal, intravesical portion of the ureter (Figure 10). Eighty percent of ureteroceles drain the upper pole of a duplex kidney (two collecting systems). Sixty percent of ureteroceles have an ectopic orifice in the urethra. A UTI in the first few months of life is a common presenting sign for a child with a ureterocele. Sometimes the obstructed upper pole drained by a ureterocele is so hydronephrotic that it is palpable as an abdominal mass.

![Figure 10. Example of a left sided ureterocele.](From: kidney.niddk.nih.gov)

Ureteroceles are usually diagnosed by ultrasonography, which typically shows a cystic intravesical mass in the posterior bladder, a dilated proximal ureter, and a hydronephrotic or dysplastic upper pole of a duplex kidney.
IVP may demonstrate the “drooping lily” sign, which is a lower pole collecting system displaced downward by a dilated upper pole. This sign can also be observed on VCUG, since up to 50% of ipsilateral lower pole moieties will reflux.
Treatment of ureteroceles is guided by clinical presentation and remaining kidney function. Infants and children presenting with sepsis are initially treated with endoscopic incision of the ureterocele to drain it and relieve obstruction. Ureteroceles draining nonfunctioning upper pole moieties can be treated by removal (heminephrectomy and ureterectomy) and the ureterocele itself can be removed through open reconstruction.

**Ectopic Ureters**

A ureteral orifice is classified as ectopic when it lies caudal to the normal insertion of the ureter on the trigone. Most (70%) of ectopic ureters are associated with complete ureteral duplication. In addition, contralateral duplication occurs in 80% of cases. Ectopic ureters insert along the pathway of the developing mesonephric duct system. Hence, in boys, the orifice can lie in the bladder neck, prostate, or epididymis. In girls, the orifice usually inserts in the bladder neck, urethra, vagina, cervix, or uterus. Boys with ectopic ureters typically present with UTI or epididymo-orchitis, depending on whether the ectopic orifice is located in the genital ducts. Infant girls often present with UTI, whereas older girls present with incontinence because the ureteral orifice is distal to the bladder neck. Abdominal ultrasonography often shows a dilated ureter draining a dysplastic or normal upper pole kidney of a duplex system. If the ectopic ureter drains a single system, the kidney may be dysplastic. VCUG often demonstrates reflux in the ectopic system, and may reveal the “drooping lily” sign. Finally, a MAG-3 study can estimate upper pole function before embarking on surgery.
Surgical management of ectopic ureters is determined by the presence or absence of ureteral duplication, as well as by the function of the subtended kidney. Many upper pole ectopic segments are nonfunctional and are treated by heminephrectomy and ureterectomy or observation. Ectopic ureters draining single systems can be reimplemented in the bladder if they drain functional kidneys. Otherwise, nephroureterectomy or observation could be chosen.

Neuropathic Bladder

Neuropathic bladder can be caused by spinal cord-based disorders such as myelomeningocele and traumatic spinal cord injury. Secondary reflux and incomplete bladder emptying from poor bladder function increases the risk of pyelonephritis. In children with spina bifida and neuropathic bladder, there may be sacral bony defects or simply pigmentation, dimples, lipomas, or tufts of hair. Often, neuropathic bladder due to spinal cord injury or occult spinal dysraphisms, such as a tethered spinal cord or spinal syrinx is discovered after evaluation of orthopedic problems, difficulty walking, or urinary retention, incontinence or UTI. Management of neuropathic bladder includes neurosurgical intervention, anticholinergic medication, and intermittent catheterization. These patients require particularly careful long-term follow-up of urinary tract function to prevent renal failure from obstructive uropathy.

Posterior Urethral Valves

Posterior urethral valves (PUV) are the most frequent cause of congenital bladder outlet obstruction. PUV are obstructing, membranous folds within the lumen of the prostatic urethra, and only occur in boys (Figure 14). Antenatal ultrasound showing a distended, thick-walled fetal bladder and bilateral hydronephrosis is suggestive of PUV.

Figure 14: VCUG showing posterior urethral valves (arrow) in a boy.

Oligohydramnios often indicates poor fetal renal function and can lead to pulmonary hypoplasia and postnatal respiratory distress. Clinical presentation after birth includes
respiratory difficulty, sepsis, renal failure, and a distended bladder. Less affected boys can present with recurrent UTI or urinary incontinence. One half to one-third of boys with PUV also have VUR and/or renal dysplasia. Acutely ill neonates with PUV are treated by placing a small feeding tube into the bladder. Definitive early treatment consists of primary endoscopic valve ablation. Other options include cutaneous vesicostomy or bilateral ureterostomies followed by later endoscopic valve ablation. Persistent bladder dysfunction after valve ablation (“valve bladder syndrome”), is an irreversible detrusor alteration from fetal bladder outlet obstruction. The potential for valve bladder syndrome and renal dysplasia leading to renal failure in boys with PUV mandates careful life long follow-up.

Prune Belly Syndrome

Also known as Eagle-Barrett syndrome, this disorder features a deficiency or absence of abdominal wall musculature; dilation of the ureters, bladder, and urethra; and bilateral undescended testes. Renal dysplasia, pulmonary hypoplasia, poor bladder function, and susceptibility to UTI and respiratory tract infections are common. Patients are diagnosed in utero with urinary tract dilation on ultrasound, or noted at birth to have wrinkled, prune-like abdominal wall skin from lack of abdominal wall musculature (Figure 15).

Evaluation with VCUG to check for VUR should be considered, but catheterization may result in introduction of bacteria into a stagnant urinary tract. DMSA scans are less invasive and can evaluate renal scarring. In mildly affected patients, lifelong antibiotic prophylaxis may be necessary. More severely affected patients who survive beyond the neonatal period often also require abdominal wall and urinary tract reconstruction along with orchidopexy. In select patients, clean intermittent catheterization may be helpful.
Urachal Remnants

The urachus is the remnant of the allantoic duct, which extends from the anterior bladder wall to the umbilicus. Typically, the urachus obliterates into a fibrous band, but on occasion some or all of this structure persists. A patent urachus may result from bladder outlet obstruction, but more commonly is not associated with other anomalies. The classic presentation is a neonate with a constantly wet umbilicus that leaks during crying or straining. Partially involuted urachal remnants can present later in childhood with infection or growth from accumulation of desquamated tissue. Symptoms include pain, fever, umbilical drainage, periumbilical mass, and UTI. Abdominal ultrasound and VCUG typically reveal urachal remnants, and contrast fistulography may also delineate these structures. Surgical resection is the treatment of choice. Urachal remnants are also known to develop adenocarcinomas.

ACQUIRED CAUSES OF UTI

Urinary Stones

In the U.S., urinary calculi occur more often in children from metabolic disorders, whereas in Europe, they tend to occur more frequently in children with UTI. Known metabolic abnormalities that predispose to stone formation include hypercalciuria, hyperoxaluria, hypocitraturia, hyperuricosuria, cystinuria, and low urine volume. Symptoms can include fever, dysuria, frequency, urgency, flank pain, hematuria, and UTI, although flank pain often is not seen in children under the age of 5. Approximately 78% of pediatric stones are located in the kidney. The most common stone types, in order of frequency, are calcium oxalate, calcium phosphate, and struvite. Renal and bladder ultrasound can identify stones, although in larger children, distal ureteral stones may be difficult to see. A KUB can reveal most stones, although pure uric acid stones are radiolucent. CT scans show nearly all stones and also provide anatomic detail that may be useful for operative planning. Spontaneous passage of stones occurs in up to half of children within 2 weeks of diagnosis. Otherwise, removal or lithotripsy of obstructing calculi can be performed through shock wave lithotripsy, percutaneous nephrolithotomy, or cystoscopy and ureteroscopy for bladder and ureteral stones, respectively. Long-term prevention of stones depends on the exact metabolic abnormality but often includes increasing water intake and decreasing salt intake.

Sexual Abuse

An estimated 1 in 4 girls and 1 in 10 boys will suffer sexual abuse before adulthood, and there are no predictive socioeconomic factors. Sexual abuse causing UTI should be considered in children with genital, perineal or anal bruising, abrasions, or lacerations. Abused children may also present with secondary incontinence (i.e., wet after at least 6 months of continence), low self-esteem, and a pathologic fear of
examination. Suspected cases of sexual abuse must be reported to child protection services.

**SUMMARY**

- UTI’s affect many children and have a significant healthcare impact.
- Bacterial UTI’s are associated with structural abnormalities of the urinary tract and also with acquired causes such as dysfunctional voiding, urinary stones and sexual abuse.
- Fungal UTI’s have associated risk factors that include immunosuppression, underlying structural abnormalities of the urinary tract and invasive lines.
- Bacterial pyelonephritis carries the risk of renal scarring and subsequent renal insufficiency and hypertension.
- The most common radiologic studies for children with UTI are renal and bladder ultrasound and VCUG.
- Antibiotic treatment and prophylaxis are effective in treating and preventing UTI, but inappropriate antibiotic use has led to an increase in bacterial resistance.
- UTI may be a sentinel event signaling the existence of an underlying congenital urinary tract abnormality, and the differential diagnosis must include this possibility.
